## Sidgwick Theory

When Werner put forward his Co-ordination Theory, Electronic theory of Valency was unknown. But later on it was considered very important to bring Werner theory of Co-ordination Compounds into line with the electronic concept of valency.

In 1927 Sidgwick made notable contribution in this field. According to Sidgwick all neutral molecules or anions which were capable of being co-ordinated to the central metal ion have atoms with at least one unshared (Lone) pair of electrons in their valency shells.

The auxiliary valence of the central metal ion, arises by the donation of electron pairs by such atoms to the central metal ion, deficient in electrons.

This gives rise to a new type of Covalent bonding in which the paired electrons of the bonds are furnished by one and only one of the atoms concerned, the atom (or the ion) furnishing the electron is called the donor and the ion accepting the electron is called acceptor.

for Example.

In complex  $[\text{Co}(\text{NH}_3)_6]^{3+}$  oxidation of Co is +3.

Atomic no of Co is 27

Loss of electron in formation of  $\text{Co}^{+3}$  ion  
 $= 27 - 3 = 24$

given electrons by 6  $\text{NH}_3$  Ligands  
 $= 6 \times 2 = 12$

Hence total no electrons =  $24 + 12 = 36$   $\Rightarrow$  atomic no of Kr, which is an inert gas.

### Limitations of Sidwick's Theory

This theory cannot explain the following points.

1. When the electron pairs donated to Cobaltic ion, the negative charge should be accumulated on Cobaltic ion.
2. The electrons donated by the neutral molecules (e.g.  $\text{H}_2\text{O}$ ,  $\text{NH}_3$ ) to the central metal ion belong to the  $2s^2$  pairs which have no bonding characteristics and to excite them to a higher level would require more energy than is usually available in bond formation.
3. Cobaltic ion accepts 12 electrons while it does not have completely equivalent orbitals to get the electrons.
4. It does not explain the directional nature of the bonds.
